Overview

This work introduces a unifying design philosophy: reframing the key constituents of a cell — lithium, porosity, and electrolyte volume — as finite, coupled reservoirs that are progressively consumed through interacting degradation processes. Energy storage research is focused on the development of effective and sustainable battery solutions in various fields of technology. However, heterogeneity and mechanical degradation compromise battery durability. Batteries play a crucial role in the domain of energy storage systems and electric vehicles by enabling energy resilience, promoting renewable integration, and driving the advancement of eco-friendly mobility. This. Lithium-ion batteries (LIBs) are the backbone of electrified transport and grid-scale energy storage. Commercial designs often target energy densities of 250–300 Wh/kg, yet these gains are increasingly undermined by limitations in service life—with capacity fade often exceeding 20% within 500–1,000. The rapid deployment of battery energy storage systems has highlighted crucial knowledge gaps in battery degradation modelling, particularly for sodium-ion batteries (SIB) compared to well-established lithium iron phosphate (LFP) models. The literature in this complex topic has grown considerably; this.
